On the Smoothness and Regularity of the Chess Billiard Flow and the Poincaré Problem

Introduction

Rotation in the Square

- Internal waves are important to the study of oceanography and to the theory of rotating fluids.
- They describe how an originally unmoving fluid can move and evolve under perturbation by a periodic forcing function
- We study the behavior of a particular two-dimensional model for these internal waves, called the Poincaré problem, which forms patterns called billiard flows
- Billiard flows map points on a boundary of a given shape to another point on that boundary, with some sort of reflection or bouncing step (ex: in a game of pool)

The chess billiard map preserves the slopes of the trajectories. Each mapping b consists of traveling first on a line of slope ρ (blue), and then bouncing off the boundary at a slope of $-\rho$ (red).

The Chess Billiard Map and Rotation

We can describe the chess billiard map as a rotation of points along the boundary; the mapping from x to b(x) below can be thought of as point x being rotated counterclockwise to b(x).

The chess billiard mapping can be more formally described as traveling on lines of slope $\rho = \frac{\sqrt{1-\lambda^2}}{\lambda}$ and $-\rho = -\frac{\sqrt{1-\lambda^2}}{\lambda}$, for a $0 < \lambda < 1$. This represents one iteration of the mapping.

Definition. The *rotation number* of a chess billiard map with parameter λ and starting point p over n iterations is

$$r(p,\lambda) = \lim_{n \to \infty} \frac{d_n}{n}$$

where d_n is total fractional distance traveled around the boundary.

Proposition. The rotation number $r(\lambda)$ of the chess billiard map in a square is $\frac{\lambda}{\sqrt{1-\lambda^2}+\lambda}$.

We use the following irrational rotation condition on $r(\lambda)$.

Definition. Let r be an irrational number. We call r β -Diophantine if for all rationals p/q, with $q \in \mathbb{Z}^+$, there exist some constants β and C > 0, for which r satisfies the inequality

$$\left| r - \frac{p}{q} \right| \ge \frac{C}{q^{2+\beta}}.$$

We quantify the rotation using the rotation number r, or the average rotation per mapping over time. For example, in the above figure, the rotation number is $r = \frac{1}{2}$.

"Rational" and "irrational" rotation correspond directly to the rationality or irrationality of r. When r is rational, a period trajectory forms — the same lines are traveled along again and again. However, in an irrational rotation (i.e. r is irrational), a point can never be mapped to itself again, so there is no periodic trajectory.

Here, the rational rotation (left) has clear lines, while the near-irrational (right) is almost fully shaded and smooth. In my project, I show that in the case of irrational rotation, the flow becomes mathematically smooth.

The Wave Equation

I studied the wave equation known as the Poincaré problem, which models the chess billiard maps:

• Loosely, r being Diophantine means that it is far from all rationals.

Statement of Main Result

Our main result is: Given a Diophantine-irrational rotation of the chess billiard map in the square, the solution to the wave equation is smooth, or infinitely differentiable.

More formally, we have the following theorem, where C^q represents qtimes differentiable.

Theorem. Given a forcing function $f(x) \in C^s[0,1] \times [0,1]$ and a β -Diophantine rotation number $r(\lambda)$ for some β and C > 0, the solution u(t) of the Poincaré problem in the square is in $C^{s-1-\beta}$.

Proof. A rough roadmap of the proof is

- Write u as the sum of exponentials (specifically, as its Fourier) decomposition)
- Bound these sums (using the Diophantine irrational condition)
- Relate the bounds to smoothness (specifically, using Sobolev spaces; bounded Fourier coefficients can translate to higher differentiability)

Corrollary. If f is smooth (i.e. $f \in C^{\infty}$), then u is also smooth.

Future Directions

The natural extension of these results is to examine the behavior of uand irrational rotation in shapes beyond the square.

$$(\partial_t^2(\partial_{x_1}^2 + \partial_{x_2}^2) + \partial_{x_2}^2)u = f(x)\cos\lambda t,$$

 $\mathbf{u}|_{t=0} = \partial_t u|_{t=0} = 0,$ $u|_{\partial\Omega} = 0,$

where Ω is a smooth 2D convex domain with boundary $\partial \Omega$, f(x) is the forcing function, and $\lambda \in (0, 1)$ is the frequency of the periodic forcing in $\cos(\lambda t)$.

- *u* represents the chess billiard map and is the solution to the Poincaré problem.
- u is the "stream function" and maps the fluid's velocity in two dimensions.
- It is what I show is highly differentiable (smooth).

All uncited images and figures created by author.

Conjecture. For all convex shapes, u is smooth for sufficiently irrational rotation.

- Studying the wave behavior is more difficult in shapes where rotation numbers cannot be explicitly calculated.
- I ran numerical simulations to estimate $r(\lambda)$ at different λ for "perturbed" squares, such as a trapezoid, tilted square, and rounded square.

I'd like to perform more simulations to determine approximate $r(\lambda)$ and analyze rapid decay of the Fourier coefficients beyond the square.
